

Lower-Frequency Macroeconomic Fluctuations: Living Standards and Leisure

Benjamin A. Malin*

August 6, 2008

Abstract

Although it is well known that aggregate variables have slow-moving stochastic components, research on macroeconomic fluctuations has focused primarily on high-frequency movements of the data. I document some interesting lower-frequency facts in U.S. post-war data and investigate whether dynamic stochastic general equilibrium (DSGE) models can explain these facts. One fact of particular interest is that hours worked per capita is negatively correlated with both output per capita and total factor productivity (TFP) at lower frequencies, in stark contrast to the positive comovement of these three variables at high frequencies. I show that this lower-frequency fact is puzzling for many DSGE models and explore a variety of candidate solutions to this puzzle. I demonstrate that preferences which depend on a time-varying reference level of consumption (i.e., a “living standard”) can rationalize the observed patterns. Finally, I discuss the relative merits of the “living standards” interpretation of the model to alternative interpretations.

I am grateful to my advisors, Pete Klenow, Bob Hall, and Narayana Kocherlakota, for their guidance and support. I would also like to thank Soo Lee, David Lopez-Salido, Felix Reichling, Esteban Rossi-Hansberg, Todd Schoellman, Azeem Shaikh, John Taylor, Michele Tertilt, Mark Wright, and seminar participants at the CBO, Cleveland Fed, Haverford, 2006 SED Meetings, Stanford, Tufts, UCSB, and USC for helpful comments. This is a revised version of the second chapter of my doctoral dissertation, and I am thankful for the financial support of the Kohlhausen Fellowship Fund during my time at Stanford. The views expressed in this paper are my own and do not necessarily represent those of the Board of Governors or the staff of the Federal Reserve System.

1 Introduction

This paper investigates lower-frequency macroeconomic fluctuations: that is, movements in aggregate variables at frequencies below the business cycle but above long-term trend. The dynamic stochastic general equilibrium (DSGE) models that modern macro uses to understand business cycles have implications for the movements of economic variables at *all* frequencies and thus provide a natural framework for this investigation.

I begin by documenting some interesting facts about lower-frequency fluctuations in postwar U.S. data. One fact of particular interest is that extended periods of rapid (stagnant) total factor productivity (TFP) growth are accompanied by fast (slow) growth in output per capita and prolonged decreases (increases) in hours worked per capita. Thus, at lower frequencies, hours worked are negatively correlated with both TFP and output. This is in stark contrast to the well-known, strong positive correlation between these three variables at high frequencies.¹

Business cycle models have been constructed to capture this high-frequency comovement, but these models generate a positive correlation between labor input and TFP/output at lower frequencies as well. In order to explore a number of candidate solutions to this model failure, I consider a prototype model that allows for various specifications of primitives (i.e., preferences, technology, government, and the stochastic shock processes). One special case is a textbook real business cycle (RBC) model, e.g., Cooley and Prescott (1995), which proves useful for illustrating why standard models perform poorly at lower frequencies. The challenge is then to identify the ingredients that help explain the lower-frequency patterns and to provide an economically meaningful interpretation of these ingredients.

The key relationship in the model is the equilibrium condition equating the marginal cost of an extra hour of market work to its marginal benefit. This can be written as

$$mpl_t = wedge_t + mrs_t,$$

where mpl denotes the (log) marginal product of labor and mrs denotes the “standard” (log) marginal rate of substitution between consumption and leisure. By “standard”, I mean the marginal rate of substitution is a time-invariant function of market consumption and market hours worked. In the textbook RBC model, the wedge is 0 in all periods, but more generally, it can vary over time. The wedge may reflect deviations between the marginal product of labor and the real wage paid by firms (e.g., due to sticky prices), deviations between the wage and the household’s marginal rate of substitution (e.g., due to labor income taxes, efficiency

¹A precise definition of high- and lower-frequency fluctuations is provided in Section 2.

wages, or wage setting by unions), or deviations between the household’s true marginal rate of substitution and the “standard” measure (e.g., due to habit formation or home production).

To generate the patterns in the data, the model must have a wedge that is positively correlated with and at least as volatile as TFP at lower frequencies. I consider whether any of the aforementioned causes of the wedge have these features. Some explanations of the wedge, such as price stickiness and efficiency wages, can be ruled out on theoretical grounds. I show that others, such as labor income taxes, do not exhibit the required patterns, at least for postwar U.S. data. Finally, drawing on the idea of a reference level of consumption from the habit formation literature, I show that preferences with a time-varying living level norm that closely tracks the permanent component of TFP can rationalize the lower-frequency fluctuations in the data.² This formulation of the reference norm is meant to capture the idea that extended periods of fast economic growth can lead to a preference shift, causing individuals to consume (given their income level) more goods and/or leisure.

I am certainly not the first to consider the role of the labor wedge in explaining movements in aggregate data. Hall (1997) demonstrates that this wedge varies significantly over time and presents evidence of its importance for explaining employment fluctuations over the business cycle. A number of papers have followed Hall’s analysis by building DSGE models that are explicit about the sources of high-frequency variation in the wedge [see Chari, Kehoe, McGrattan (2004), Gali, Gertler, Lopez-Salido (2005) and references therein]. On the other hand, the model presented herein is the first to analyze the lower-frequency movement of the labor wedge in a general equilibrium framework. Mulligan (2002) and Gali (2005) have also written on the lower-frequency labor wedge, but the use of a DSGE model is beneficial as it facilitates accounting for the movements of a number of aggregate variables in response to driving forces.

To construct lower frequency fluctuations, I remove a linear trend (a fluctuation of infinite periodicity) and fluctuations more frequent than every 32 quarters from the data. Although this approach to characterizing slow-moving fluctuations is novel, the interest in sub-cyclical movements is not. King, Plosser, and Rebelo (1988) look at linearly detrended data and mention the low correlation between hours and output, and Hall (1997) uses a polynomial decomposition of time series to construct “medium frequency” fluctuations that are qualitatively similar to my lower frequency fluctuations. Neither of these papers focus on building a model to explain the fluctuations below business cycle frequencies. Comin and Gertler (2004) build

²Section 5.1 describes one way of decomposing TFP into permanent and transitory components. One can think of the living level norm as a reference point that adjusts smoothly over time (hence, the omission of changes in economic performance that are considered temporary) and that is significantly influenced by the average level of living in society as a whole.

a model to explain many features of “medium term” business cycles, defined as fluctuations of periodicity less than 200 quarters.

Economists have much to gain from understanding lower-frequency fluctuations. Because DSGE models have predictions for fluctuations at all frequencies, lower frequencies could be used to discipline business cycle models and possibly distinguish between alternative business cycle theories. This discipline would also be useful for improving these models as tools for policy analysis and for analyzing specific episodes of interest, such as the large increase in labor input in the 90s, as part of lower-frequency changes in the economy. To this end, one key contribution of this paper is extending the scope of DSGE models to evaluate sub-cyclical movements. This requires using solution methods that can handle persistent deviations from the balanced growth path.

Section 2 documents some facts about lower-frequency fluctuations in postwar U.S. data, including the negative correlation of hours worked with both TFP and output. Section 3 presents a prototype DSGE model, which serves as a unifying framework for considering various explanations of the facts. Section 4 demonstrates that the lower-frequency relationship between hours worked and TFP/output is a puzzle from the view of a textbook RBC model. Moreover, variants of the textbook model found in the business cycle literature do not provide satisfactory explanations of the puzzle. Section 5 demonstrates how a living-standard model resolves the puzzle and discusses various interpretations of the model. In Section 6 I offer some concluding remarks, and Sections 7 and 8 describe the data construction and technical aspects of the model in more detail.

2 High- and Lower-Frequency Facts

In this section I define high- and lower-frequency fluctuations and then describe some key stylized facts that emerge from postwar U.S. data. I use a band-pass filter (Baxter and King 1999) and a linear time trend to decompose individual time series into three parts: variations at frequencies between 2 and 32 quarters (high frequencies), those between 32 and an infinite number of quarters (lower frequencies), and the linear trend (the zero frequency). Figure 1 shows this frequency decomposition in the time domain. It plots log real GDP per capita, the trend associated with a high-pass filter with cutoff frequency of 32 quarters [HP (32)], and a linear trend. The decomposition of the data into high and lower frequencies is given by

$$\begin{aligned} \text{Data} &= \underbrace{\text{Data} - \text{HP}(32) \text{ Trend}} + \underbrace{\text{HP}(32) \text{ Trend} - \text{Linear Trend}} + \text{Linear Trend} \\ &= \text{High Frequencies} + \text{Lower Frequencies} + \text{Linear Trend}. \end{aligned}$$

This definition of high and lower frequencies is useful for a couple of reasons. At the high end of the frequency spectrum, the choice of 32 quarters as the cutoff between high and lower frequencies enables a comparison with business cycle studies that filter the data with a Hodrick-Prescott filter, a close approximation to a high-pass (32) filter.³ At the low end, neoclassical growth theory predicts that variables will grow at a constant rate (i.e., with a linear trend) in the absence of shocks. Finally, with this three-way decomposition, none of the movements in the data are excluded from the analysis. DSGE models have implications for fluctuations at all frequencies, and this decomposition will provide a compact, albeit stylized, way of comparing fluctuations from model simulations with those in the data.

I focus on the volatility, persistence, and comovement of a set of aggregate variables including output, consumption, investment, hours worked, labor and total factor productivity, and the net real return to capital. Tables 2 and 3 display a set of moments for the high- and lower-frequency fluctuations of each of these variables. I use quarterly data from 1947:1 - 2008:1, but the reported moments cover 1950:1 - 2005:1 because the high-pass trend is a moving average which requires three years of both past and future data.⁴

The tables display some interesting statistics. First, the lower-frequency fluctuations are large; in fact, for all variables except investment, the lower frequencies are more volatile than the high frequencies. Second, the correlation between productivity (both labor and total factor) and output is higher at lower frequencies. This fact will lead me to consider a model in which changes in productivity have a central role in driving the lower-frequency fluctuations.

The most striking difference between the moments at different frequencies is the comovement between hours worked and output. At high frequencies, these two variables exhibit a strong positive correlation (0.86), but at lower frequencies, they are modestly negatively correlated (-0.31). The same relationship holds between hours worked and TFP, which display a positive correlation (0.11) at high frequencies and a stronger negative correlation (-0.61) at lower frequencies. Relatedly, both labor productivity and TFP are less volatile than output at high frequencies but more volatile at lower frequencies. At high frequencies, the positive comovement of productivity and hours worked leads to output fluctuations which are amplified relative to productivity, while the negative comovement at lower frequencies is associated with dampened output fluctuations.

Figures 2 - 4 shed light on the differences between the high- and lower-frequency comove-

³As noted by King and Rebelo (1999), a fairly conventional definition of the business cycle, following Burns and Mitchell (1946) and Prescott (1986), is fluctuations in economic time series that have a periodicity of eight years or less.

⁴The data appendix (Section 7) provides a detailed description of the construction of all variables.

ments of hours worked with output/TFP. The top panel of Figure 2 shows the deviations of log real GDP per capita and log hours worked per capita from their respective linear trends, while the bottom panel replaces log GDP with log TFP.⁵ Recall that removing a linear trend leaves *both* the high- and lower-frequency fluctuations, and thus, the linearly detrended series are a compact way to display all fluctuations at once. The positive relationship between TFP/GDP and hours worked from quarter to quarter (high frequencies) and the negative relationship from decade to decade (lower) are evident in Figure 2.

Figure 3 shows the high and lower frequencies of GDP and hours worked. At high frequencies, hours worked and GDP move together, while at lower frequencies, hours worked are high when output is low and vice versa. Figure 4 replaces GDP with TFP. The plots reflect the weak positive correlation between TFP and hours at high frequencies and the negative correlation at lower frequencies. The high-frequency relationship between hours worked and output should come as no surprise: recessions (expansions) are times of low (high) market output and market work, and TFP is positively correlated with both variables, although its correlation with hours worked is relatively weak. The lower-frequency relationship between these variables may be surprising, but it is influenced by two well-known patterns. First, output and productivity grew faster than average during the 50s and 60s and then slowed over the next 25 years. Thus, relative to a linear trend, these variables were high in the 60s and 70s. Second, hours worked fell from 1951 to 1975 and then gradually rose, reaching their initial level in the late 90s.⁶

Another way to quantify these patterns is to compute the comovement of the growth rates of the lower-frequency fluctuations. These include $Corr(\Delta Y, \Delta N) = 0.51$, $Corr(\Delta Y, \Delta A) = 0.73$, and $Corr(\Delta A, \Delta N) = -0.10$. The negative correlation between the growth rates of TFP and hours worked will be useful for evaluating the performance of the theoretical models studied in later sections. It is also interesting to note the growth rates of the lower-frequency fluctuations of these two variables have opposite signs in 55% of the quarters in the sample period. Lower-frequency TFP and hours worked move together at the major turning point of the productivity series (early 70s) and for brief periods of vigorous expansions (mid 60s) and severe recessions

⁵Note that the trend in hours worked per capita over this sample period is basically zero (-0.015%), so the raw data series for hours looks virtually identical to the detrended series in the figures. Moreover, the hours worked moments reported in Table 3 do not change significantly if a linear trend of 0 is removed rather than the actual linear trend.

⁶The literature on the productivity and output growth slowdown is so expansive that I opt not to list references. The U-shaped pattern in hours worked can be found in King et. al. (1988) and Ingram et. al. (1997). Both studies use an hours worked series constructed using data from the Current Population Survey. McGrattan and Rogerson (2004) find a similar pattern in decennial census data.

(early 80s), but they generally move in opposite directions.

To summarize, the lower-frequency comovement of hours worked with output and TFP is very different than the comovement of these variables at business cycle frequencies. At lower frequencies, the fast productivity growth of the 50s and 60s was accompanied by rapid growth in output per capita and decreasing hours worked per capita. The slower productivity growth from the 70s through the 90s coincided with slower growth in output and, after a decline in the early 70s, a gradual increase in hours worked through the end of the sample period. As I will show in Section 4, many business cycle models have predictions for lower-frequency fluctuations that are at odds with the data. Because models of economic fluctuations have predictions for a number of aggregate variables, a satisfactory explanation of the lower-frequency comovements will also be required to be roughly consistent with other moments reported in Tables 2 and 3.

2.1 Robustness Checks

The definitions of aggregate variables in the previous section are fairly standard in the business cycle literature, but the inclusion of lower-frequency fluctuations in the analysis raises the question of whether alternative definitions would have much impact on the statistics reported above. I briefly discuss the most notable alternatives and the impact they have on the lower-frequency facts.

2.1.1 Definition of Per Capita

In Section 2, the population was taken to be individuals of age 16-64, a natural choice amongst popular alternatives, namely individuals older than 16 and those of all ages, for two reasons. First, some measure of the working age population seems more appropriate than using total population when one of the objectives is to explain labor input, especially if one's model abstracts from the decision to send children into the workforce. Second, the ages 16-64 were chosen rather than 16 and above because compositional changes in the age of the population have occurred over the sample period, while the primary age of retirement has remained 65 years of age.

The alternative definitions of the population, however, do not significantly change the facts reported above. The moments reported in Tables 2-3 are qualitatively similar, while the figures change only slightly. When the total population is used rather than the working-age population, hours worked per capita reaches its trough between 1967-1971 rather than 1975-1980. When retirement-aged individuals are included in the population, hours worked per

capita are not as high in the 90s as they are in the figures above. The stylized fact that lower-frequency TFP and output per capita are high (low) when hours worked per capita are low (high), however, is robust to these changes.

2.1.2 Including the Public Sector

The statistics reported above were for the private sector, but one may be concerned that these statistics omit important changes in the size of the public sector over the postwar period. I thus consider broader measures of the aggregate variables, with the most notable changes being (i) hours worked are total domestic hours rather than total private sector hours and (ii) government capital and consumer durables are included in the capital stock while the flows of services from these stocks are included in output.⁷ The main changes in the statistics reported above are that the lower-frequency correlation of hours worked with output and TFP are not as low: 0.01 and -0.28, respectively. Because of the increase in government hours worked in the 50s and 60s, labor input did not decrease as rapidly. Still, hours were decreasing over this period while TFP grew extremely quickly. Moreover, I will show that the lower-frequency correlations are still substantially lower than what is predicted by standard business cycle models.

2.1.3 Definition of Leisure

Ramey and Francis (2005) consider more involved constructions of both the numerator and denominator of hours worked per capita. For the denominator, they argue that if one wants to limit the time endowment to the potential workforce (as opposed to including the total population), it should be done in a consistent manner that reflects the ability to engage in productive activities. Thus, they adjust the time endowment of individuals to reflect health as well as age. For the numerator, they adjust hours worked to include government work, time spent in formal schooling, and work at home. Their calculations imply significant changes to the time series for leisure, the biggest of which occur during the first half of the 20th century. For the time period under consideration here (1947-2005), their time series for leisure and mine (simply the constant per period time endowment minus time spent in market work) have qualitatively similar movements.

⁷See Section 7 for complete details on the data construction.

3 The Prototype Model

Formal general equilibrium models require an explicit characterization of technology, the stochastic impulses that shock the economy, preferences, the information available to economic agents, and the market structure. Because of the wide range of possible specifications for each of these components, multiple explanations of the stylized fact documented in the previous section may exist. In this section I describe a unifying framework for evaluating many potential explanations and discuss the methods used to solve the model.

3.1 Environment

I consider a closed-economy stochastic neoclassical growth model. There is a single output good that is used for consumption, investment, and government spending, and the aggregate resource constraint for the economy is $C_t + I_t + G_t = Y_t$. The government funds its expenditures by levying distortionary taxes on income. All economic agents are price takers and have perfect information about the state of the economy.

3.1.1 Technology

The aggregate production technology is given by

$$Y_t = A_t^{1-\alpha} F(K_t, N_t) = A_t^{1-\alpha} K_t^\alpha N_t^{1-\alpha} \quad (1)$$

where Y_t is output, K_t is the physical capital stock, N_t is labor input, and $A_t^{1-\alpha}$ is an index of TFP.⁸

The capital accumulation technology is

$$K_{t+1} = (1 - \delta)K_t + I_t. \quad (2)$$

3.1.2 Stochastic Driving Force

Following Kydland and Prescott (1982), random shocks to productivity are taken as the driving force of the model's fluctuations. TFP evolves according to a Markov process

$$A_t = \gamma_t^A A_{t-1},$$

⁸ A_t is raised to an exponent of $1 - \alpha$ simply to allow for a cleaner normalization of the model's variables in the process of making them stationary for the solution procedure.

where the growth rate of TFP γ_t^A is exogenous and drawn from distribution Γ_t^A . Various specifications of Γ_t^A are used in the business cycle literature, and I will consider some alternatives below. Throughout I use the notation γ^V to denote the growth rate of a variable V .

3.1.3 Preferences

There is a representative household whose preferences are given by

$$\max_{\{C_t, N_t\}} E_0 \sum_{t=0}^{\infty} \beta^t u(C_t, N_t; X_t),$$

where the momentary utility function is

$$u(C_t, N_t; X_t) = \frac{\left[\kappa + \frac{\left(\frac{C_t}{X_t}\right)^{1-\eta}}{1-\eta} - b \frac{N_t^{1+\nu}}{1+\nu} \right]^{1-\frac{1}{\sigma}} - 1}{1 - \frac{1}{\sigma}} \quad (3)$$

with $\nu, b > 0$, $\sigma \geq 0$, and $0 \leq \eta \leq 1$, and in the case $\eta = 1$ or $\sigma = 1$, the appropriate power function is replaced by the log function. The constant κ is set to ensure that the marginal utility of consumption is always non-negative.⁹ Besides noting that the household takes it as an exogenous state variable, I postpone discussion of X for a few paragraphs.

The parameters of the utility function govern the household's choice of consumption and labor supply as follows: ν is a determinant of the compensated wage elasticity of labor supply; η governs the income elasticity of labor supply; b is a scaling parameter used to set the steady state level of labor supply; and conditional on the other parameters, σ governs the (average) willingness of the household to substitute consumption through time.¹⁰

This momentary utility function nests several specifications used in the literature. For example, if $\eta = 1$ and $\sigma = \infty$,

$$u(C_t, N_t; X_t) = \ln(C_t) - b \frac{N_t^{1+\nu}}{1+\nu} - \ln(X_t).$$

With these parameter values, X enters the utility function in an additively separable way and has no effect on the household's decisions. In this case, $\frac{1}{\nu}$ is the Frisch elasticity of labor supply. A further special case is the reduced-form of the indivisible labor model of Rogerson (1988) as

⁹ κ will be set to 0 in all the specifications of the model considered in the subsequent sections.

¹⁰For parameterizations in which preferences are nonseparable, the intertemporal elasticity of substitution (IES) will depend upon allocations and will vary over time. σ is chosen so that the model's steady-state IES is consistent with estimates of the IES from the literature.

used by Hansen (1985), which is obtained by setting $\nu = 0$.¹¹ If instead, $\eta = 0$ and $\sigma = \infty$, utility takes the functional form used by Greenwood, Hercowitz, and Huffman (1988).

Models with state variables in preferences are common in macroeconomics. Examples include models with ‘habit formation’ [e.g., Abel (1990,1999); Campbell and Cochrane (1999)], home production [e.g., Benhabib, Rogerson and Wright (1991)], and leisure-enhancing production [Greenwood and Vandenbroucke (2005), Kopecky (2005)]. In Section 5, I consider alternative functional forms for and economic interpretations of the state variable X , but for now just note that, as long as X does not enter the utility function in a separable way, it affects both the marginal rate of substitution (MRS) between consumption at different dates and the MRS between contemporaneous consumption and leisure. It can be shown that an increase in the living standard increases both marginal rates of substitution: increasing the taste for current consumption relative to future consumption and for leisure relative to contemporaneous consumption.

Empirical observations motivate restrictions on the functional forms that X can take. In the long-run, many aggregate variables grow at roughly the same rate (Kaldor 1957) while leisure is relatively constant (Ramey and Francis 2005). For the model to have a balanced growth path (BGP) in which leisure is constant ($\gamma^N = 0$) while trending variables grow at the same rate (i.e., $\gamma^C = \gamma^K = \gamma^I = \gamma^Y = \gamma^A \equiv \gamma$), either $\eta = 1$ or $\gamma^X = \gamma$.¹² $\eta = 1$ is the well-known requirement pointed out by King, Plosser and Rebelo (1988a) for obtaining a BGP when preferences are a stable function of only consumption and leisure. This requires that the income and substitution effects of a change in the wage are directly offsetting. Based on estimates of income and substitution effects from the labor supply literature (Blundell and MaCurdy 1999),¹³ the relaxation of this requirement appears to have some merit. By including a trending variable in preferences that grows at the same rate as other trending variables in the long-run, the model can exhibit balanced growth without requiring $\eta = 1$.

¹¹A utility function of the form $u(C_t, N_t) = \ln(C_t) + \ln(\bar{N} - N_t)$, where \bar{N} is the per period time endowment, is closely approximated by the momentary utility function (equation 3) with parameters $\eta = 1$, $\sigma = \infty$ and $\nu = 0.25$.

¹²The requirement that either $\eta = 1$ or $\gamma^X = \gamma$ is derived from evaluating the first-order condition for labor supply, $-\frac{u_N(C_t, N_t; X_t)}{u_C(C_t, N_t; X_t)} = A_t^{1-\alpha} F_N(K_t, N_t)$, along a balanced growth path of the model.

¹³Tables 1 and 2 of Blundell and MaCurdy (1999) report estimates of the uncompensated wage elasticity and income elasticity from a number of studies. The income elasticity (income effect) is typically substantially smaller in magnitude than the uncompensated wage elasticity (substitution effect).

3.1.4 Government

The government raises revenues by levying distortionary taxes on capital and labor inputs and uses these revenues to fund its expenditures. Unused revenue is rebated lump-sum to households in each period, so that budget balance holds. The government is fully characterized by its budget constraint

$$G_t + TR_t = \tau_{N,t}W_tN_t + \tau_{K,t}R_tK_t,$$

where TR_t are lump-sum transfers to households, $\tau_{N,t}$ and $\tau_{K,t}$ are distortionary taxes on labor and capital income, and W_t and R_t are the wage and return to capital. From the view of private agents, tax rates, transfers, and spending are exogenous processes, and for simplicity, agents expect that future taxes and transfers (relative to total output) will remain at their current rates.

3.2 Equilibrium

It is straightforward, but tedious, to define a competitive equilibrium for this economy. Therefore, I simply state the necessary conditions that any competitive equilibrium allocation $\{C, K, N\}_{t=0}^{\infty}$ must satisfy.¹⁴ These include

1. the intertemporal Euler equation

$$1 = \beta E_t \left\{ \frac{u_C(C_{t+1}, N_{t+1}; X_{t+1})}{u_C(C_t, N_t; X_t)} [(1 - \tau_{K,t+1}) A_{t+1}^{1-\alpha} F_K(K_{t+1}, N_{t+1}) + 1 - \delta] \right\}, \quad (4)$$

2. the intratemporal equilibrium condition

$$-\frac{u_N(C_t, N_t; X_t)}{u_C(C_t, N_t; X_t)} = (1 - \tau_{N,t}) A_t^{1-\alpha} F_N(K_t, N_t) \quad (5)$$

3. and the resource constraint

$$C_t + K_{t+1} - (1 - \delta)K_t + G_t = A_t^{1-\alpha} F(K_t, N_t). \quad (6)$$

3.3 Solution Method

I use recursive methods to solve for the equilibrium, and thus, it is necessary to transform the model so that all variables are stationary. This is done by scaling all trending variables by

¹⁴A full characterization of the equilibrium allocation would also include initial and transversality conditions. Note that equilibrium prices are given by the marginal product of the production technology with respect to the relevant inputs.

the variable X_t . A “hat” over a variable represents the stationary version of that variable (e.g. $\widehat{C}_t = \frac{C_t}{\bar{X}_t}$).

The recursive formulation for the problem is

$$V(S_t) = \max_{\{\widehat{C}_t, N_t, \widehat{K}'_t\}} \left\{ u(\widehat{C}_t, N_t) + \beta E_t h(\gamma_{t+1}^X) V(S_{t+1}) \right\}$$

$$\text{subject to } \widehat{C}_t + \widehat{K}'_t - (1 - \delta)\widehat{K}_t + \widehat{G}_t = \widehat{A}_t^{1-\alpha} \widehat{K}_t^\alpha N_t^{1-\alpha}$$

where $\widehat{K}'_t = \gamma_{t+1}^X \widehat{K}_{t+1}$. $S_t = \{\widehat{K}_t, \{A_t^{state}\}, \{X_t^{state}\}, \tau_{K,t}, \tau_{N,t}, \widehat{G}_t\}$, where $\{A_t^{state}\}$ and $\{X_t^{state}\}$ are sets of state variables that are needed for forming expectations and for determining current levels of productivity A and the preference variable X . Given the preference specification in equation (3), $h(\gamma_{t+1}^X) = 1$.

The model is solved numerically using policy function iteration, solving for nonlinear policy functions $\widehat{C}(S_t)$, $N(S_t)$, and $\widehat{K}'(S_t)$ over the multi-dimensional, continuous state space S_t . Specific examples of $\{A_t^{state}\}$ and $\{X_t^{state}\}$ will be given in following sections when I consider various specifications of the model’s primitives. For now, note that the specifications considered require between 2 and 8 state variables. As the number of state variables increases, one faces a curse of dimensionality. To address this computational challenge, I use Smolyak’s algorithm for approximating functions of high-dimensionality (Krueger and Kubler 2004). This algorithm has been used to solve models with up to 30 state variables, and it proves sufficient for the models considered below. For readers who are interested, a brief overview of the solution procedure and further references are provided in the technical appendix.

An alternative approach for solving models with multiple state variables is to take a linear approximation around the deterministic steady state of the economy. I choose to use a nonlinear solution method because it is more accurate in general and noticeably so for some specifications of the model. As an example, in models with very persistent shocks such as those considered in Section 5, state variables γ^X and \widehat{K} vary significantly from their steady state values for plausible realizations of productivity growth. Because the accuracy of a linearized approximation decreases as the model’s state variables move further away from their steady state values, a nonlinear solution method is preferable.

4 A Puzzle

In this section I demonstrate that the lower-frequency comovement of hours worked with output and productivity is a puzzle from the view of many DSGE specifications found in the

business cycle literature. I first use a textbook RBC model to illustrate the primary difficulty encountered by standard specifications. I then add distortionary labor income taxes to the model to demonstrate that taxes alone are not sufficient for resolving the puzzle. Finally, I show that models with more persistent productivity shocks can not resolve the puzzle without having other counterfactual predictions. This analysis points towards a DSGE specification, fleshed out in Section 5, that can rationalize the lower-frequency patterns in the data.

4.1 Textbook RBC Model

The unifying framework described in Section 3 allows for various specifications of the distribution of productivity growth shocks, preferences, and taxes. A textbook RBC model (e.g., Cooley and Prescott 1995) specifies these ingredients as follows. First, the stochastic process for TFP growth consists of transitory shocks around a constantly growing trend. Formally,

$$\gamma_t^A = \frac{A_t}{A_{t-1}} = \frac{T_t}{T_{t-1}} \frac{Z_t}{Z_{t-1}} = \gamma^T \frac{Z_t}{Z_{t-1}},$$

where γ^T is the constant growth rate of trend productivity T_t , while Z_t is a stationary cyclical component that reflects transitory shocks. Letting lowercase letters denote logged variables (i.e., $z_t = \ln(Z_t)$), log productivity growth γ^a follows a Markov process:

$$\begin{aligned} \gamma_t^a &= \mu_\gamma + z_t - z_{t-1} \\ z_t &= \rho_z z_{t-1} + \varepsilon_{z,t}, \text{ where } \varepsilon_z \sim \text{i.i.d. } N(0, \sigma_z^2), \end{aligned} \tag{7}$$

where $\mu_\gamma = \ln(\gamma^T)$. Second, preferences are defined over consumption and time spent in market work only; that is, parameters will be chosen so that X enters preferences in an additively separable way. Finally, this specification abstracts from time-varying taxes and government spending.

The state space for this model specification is $S_t = \{\widehat{K}_t, \widehat{A}_t\}$ with $\widehat{A}_t = z_t$. The current value of the transitory shock to productivity is all that is needed to form expectations of future productivity growth. Since X_t is additively separable in the utility function, it does not appear in either the intertemporal MRS for consumption or the intratemporal MRS between leisure and consumption. X_t is needed to normalize the other variables in the model, but simply letting X grow at a constant rate requires no additional state variables.

4.1.1 Choosing Parameter Values

Standard Parameters Many of the model parameters are selected to ensure agreement with observed long-run values for key postwar U.S. aggregates. These parameters will be

set the same way in all versions of model considered in this paper. The mean growth rate of technological progress, μ_γ , is chosen to imply a 2.1 percent annual average growth rate of real per capita output, and the discount factor, β , is then set to imply an average real return to capital of 7.4 percent per year. Capital's share, α , is set to 0.333, consistent with broad evidence, while the depreciation rate, δ , implies average depreciation of 6 percent per year. The parameter governing the steady-state level of labor supply, b , is set to imply an average of 23 percent of available time spent in market work. The methods used to set these parameters are quite standard and are described in Cooley and Prescott (1995).

Preference Parameters A couple of the preference parameters are pinned down by long-run restrictions or functional form assumptions. As discussed in Section 3.1, $\eta = 1$ is required for the model to be consistent with a balanced growth path in which hours worked are invariant to the level of productivity. $\sigma = \infty$ makes utility log-separable in consumption and hours worked

$$u(C_t, N_t; X_t) = \ln(C_t) - b \frac{N_t^{1+\nu}}{1+\nu} - \ln(X_t) \quad (8)$$

and implies an intertemporal elasticity of substitution (IES) of 1.¹⁵

The other parameter that governs the household's preferences for consumption and leisure is taken from estimates from microeconomic studies of labor supply. Because $\sigma = \infty$, ν is equal to the reciprocal of the intertemporal (Frisch) elasticity of labor supply. The first-order condition governing labor input (equation 5) takes the form

$$bN_t^\nu C_t = (1 - \tau_N) W_t.$$

Letting lowercase letters denote logged variables and dropping uninteresting constants,

$$n_t = \frac{w_t - c_t}{\nu}. \quad (9)$$

Using this equation, the intertemporal (Frisch) elasticity of labor supply $\frac{1}{\nu}$ is estimated to be in the 0.5-1 range (Blundell and MaCurdy 1999), so I set $\nu = 1.5$. Many business cycle researchers have argued that the elasticity of labor supply should be much larger in a representative agent model than estimated by microeconomic studies because of the importance of the extensive margin (employment vs. unemployment). Note from equation (9) that a larger elasticity will

¹⁵Many business cycle models consider preferences that do not require IES = 1, e.g., Cobb-Douglas preferences $u(C, N) = \frac{(C^\zeta(1-N)^{1-\zeta})^{1-\frac{1}{\sigma}}}{1-\frac{1}{\sigma}}$. These preferences, however, still have the feature that the intratemporal MRS is linear in consumption ($\eta = 1$), and thus, models with these preferences will perform similarly to the textbook RBC model in regards to explaining the lower-frequency comovement of labor input with output and productivity.

affect the magnitude of the labor supply response to a shock, but it will not affect the sign. Thus, the model’s implications for the lower-frequency comovement of labor input with output and TFP is robust to the choice of ν .

Productivity Parameters The parameters for the stochastic process for productivity shocks (equation 7) are chosen using standard procedures, e.g., section 4.1 of King and Rebelo (1999). The parameters are $\rho_z = 0.95$ and $\sigma_z = 0.0105$.¹⁶

The parameters for the textbook RBC specification are given in Table 4.

4.1.2 Results

I conduct two experiments to assess the model’s ability to capture the lower-frequency fluctuations observed in postwar U.S. data. First, I simulate the model many times and report the average moments across these simulations, producing tables similar to Tables 2 and 3. I also calculate the variance (across simulations) of the moments, which is useful for making statements about how (un)likely it is that the model could produce the patterns seen in the data. Second, I calculate the Solow residual from actual data and then simulate the model using this residual as the forcing process. Implicitly, I assume that the model and data are the same in terms of their Solow residual, and ask whether they are similar along other dimensions (i.e., hours worked and output). Because this experiment only uses a subset of the stochastic shocks that hit the economy, the fit between the simulated and actual data is unlikely to be extremely close. Still, this experiment will be useful for showing how endogenous variables respond to the driving force.

Tables 5 and 6 show average moments of the high and lower-frequency fluctuations across 200 model simulations. This model does not capture the different relationship that exists between labor input and output/TFP at different frequencies, as reflected by the high correlation between these variables at both the high and lower frequencies. The difference between the average correlation of labor input and output (TFP) at high frequencies and that at lower frequencies is only 0.25 (0.15). Moreover, any particular simulation of the model is unlikely to produce the lower-frequency comovement observed in U.S. data. The lower-frequency correlation of hours worked and output (TFP) in the data lies more than 10 (19) standard deviations

¹⁶Recall that the transitory shock enters the production function as $Z^{1-\alpha}$ rather than Z . Thus, the standard deviation of the transitory shocks σ_z is consistent with values typically used in the business cycle literature.

away from the average moment across simulations.¹⁷

The results of simulating the model with the actual U.S. Solow residual as the driving force are shown in Figure 5, which displays the lower frequencies of the Solow residual (TFP) series along with the hours worked and output series from the model and the data. The top panel shows significant divergences between the model's lower-frequency pattern for hours worked and the actual movements in the data. The model has difficulty replicating the sizable decrease in hours worked that took place from the start of the sample through the mid-60s and also the strong growth in hours that occurred in the last 15 years of the 20th century. When the model does produce growth in labor input at the end of the sample, actual hours were decreasing. Moreover, the correlation of the growth rates of the lower-frequencies of model hours worked and productivity is 0.45, in comparison to -0.11 in the data.

The bottom panel shows the related pattern that the model's output series is more volatile at lower frequencies than the TFP series, while actual GDP is less volatile than TFP. The lower-frequency positive correlation between TFP and hours worked in the simulation leads to the extra volatility of GDP.

The model's inability to capture the lower-frequency movements in labor input can be understood by examining the intratemporal equilibrium condition

$$n_t = \frac{w_t - c_t}{\nu} = \frac{y_t - c_t}{\nu + 1} = \frac{(1 - \alpha)a_t + \alpha k_t - c_t}{\nu + \alpha}, \quad (10)$$

where the second equality comes from the fact that the wage equals the marginal product of labor. The textbook RBC model has only one force that works against hours worked and output moving in the same direction at all frequencies: the negative wealth effect associated with a wage increase. Given the preference specification in equation (8), the wealth effect is summarized by c_t . In response to a positive transitory shock, the increase in consumption is less than that of the wage because of consumption smoothing and hours worked increase. As a result, the model is able to produce the high-frequency positive comovement of productivity, output, and labor input. During extended periods of rapid productivity growth (i.e., a sequence of mostly positive shocks) though, the same forces are at work and contrary to the pattern in the data, hours worked increase. Put differently, the wealth effect is not strong enough to explain the negative lower-frequency comovement between hours worked and output/TFP.

Although the textbook RBC model abstracts from many ingredients that are relevant for explaining features of high-frequency fluctuations (e.g., nominal and real rigidities, government

¹⁷The standard deviation (across simulations) of the correlation of lower-frequency labor input with output (TFP) was 0.10 (0.07).

spending shocks, a financial accelerator, etc.), these ingredients are typically embedded in DSGE models in ways that do not significantly change the determination of labor supply (equation 10) at lower frequencies. For example, models with sticky wages do separate the wage from the marginal product of labor, but the separation lasts for at most a few years, not for decades. There are, however, some elaborations of the textbook model, to which I now turn my attention, that could be of first-order importance for explaining lower frequencies.

4.2 Distortionary Labor Taxes

In a study of U.S. and European economies, Prescott (2004) argues that different tax codes can explain much of the disparity between the performance of these countries' labor markets over the medium-run. His study focuses on two time periods: 1970-1974 and 1993-1996. For the U.S., he finds that tax rates were lower in the mid 90s than in the early 70s, and hours worked were higher. This raises the question of whether taxes can explain the lower-frequency comovement of hours worked with output and TFP over the entire postwar sample period.

Figure 6 shows an average marginal income tax rate series for the U.S. postwar period, constructed following Barro and Sahasakul (1983), and Figure 7 shows the lower-frequency movements in hours worked that result from simulating the RBC model with the income tax rate series and TFP as driving forces. Although I use a different measure of the tax rate than Prescott, our results are consistent for the early 70s and the mid 90s. The timing of tax changes, however, does not help explain the movement of hours worked during some other sub-periods of the sample. The slight decrease in tax rates between 1950 and the mid 60s causes an increase in hours worked in the model. Moreover, increasing taxes in the 90s push hours worked down. All told, taxes do not appear to be sufficient for explaining the puzzle.

4.3 Persistent Shocks

As demonstrated by Campbell (1994), a positive shock to productivity that is *more* persistent than a random walk causes consumption to increase more than the wage as individuals dissave (i.e., borrow against higher expected future wage income). Because the intratemporal equilibrium condition implies that hours worked are inversely related to the share of consumption in output, such shocks could generate the negative correlation between lower-frequency hours worked and output/TFP. However, if the model generated that negative correlation, it must also generate a positive correlation between the consumption share and output, a pattern not found in postwar U.S. data. Figure 8 shows lower-frequency GDP and the non-high-frequency

consumption share (i.e., a linear trend is still in the consumption share). At lower frequencies, the consumption share typically moves in the opposite direction of output.

4.4 Discussion

The above analysis points the way to a potential solution of the lower-frequency puzzle. The key relationship discussed in this section has been the intratemporal equilibrium condition equating the marginal product of labor (MPL) to the MRS between consumption and leisure, where the MRS is a time-invariant, increasing function of market consumption and hours worked. Rewriting equation (10),

$$(1 - \alpha) \frac{A_t^{1-\alpha} K_t^\alpha}{N_t^\alpha} \equiv MPL_t = MRS_t \equiv bN_t^\nu C_t. \quad (11)$$

For this equation to hold during an extended period of fast TFP growth while hours worked decline requires that consumption (counterfactually) grows extremely quickly. Alternatively, there could be a wedge in the equilibrium condition; that is, $MPL_t = Wedge_t * MRS_t$. Distortionary labor taxes provide such a wedge although they do not move as needed to explain the lower-frequency fluctuations in postwar U.S. data.

Business cycle researchers have considered many explanations for this wedge at high frequencies. Examples include taxes, sticky wages, unions, home production (Benhabib, Rogerson, and Wright 1991), leisure-enhancing production [e.g., Greenwood and Vandenbroucke (2005), Kopecky (2005)] and habit formation [Lettau and Uhlig (1999); Boldrin, Christiano, Fisher (2001)]. In the next section I build on a habit formation story to develop a DSGE specification that can rationalize the lower-frequency patterns in the data.

5 A Solution

The solution to the lower-frequency puzzle presented herein considers the hypothesis that individuals derive utility from consumption and leisure relative to a “living standard”. As in models with (external) habit formation, individuals’ consumption and labor supply decisions are influenced by a state variable in preferences. Thus, the intratemporal MRS will no longer be a time-invariant function of only market consumption and hours worked; there will be a wedge between the “true” MRS and the “standard” MRS given in equation (11). This “living standard”, denoted by X_t in Section 3, will also affect the MRS between consumption at different dates, and thus, a complete general equilibrium analysis is needed to understand all its implications for aggregate fluctuations.

After describing and parameterizing a baseline living-standard model, I repeat the same experiments performed in Section 4 to measure the model’s ability to explain the lower-frequency puzzle. To demonstrate the model’s key features, I then consider various formulations and parameterizations for the living standard. Finally, I discuss the model’s interpretation of the postwar U.S. economy and the merits of alternative interpretations of the model, such as home or leisure-enhancing production stories, relative to the living standard interpretation.

5.1 “Living Standard” Model

The “living standard” model deviates from the textbook RBC model in two ways: its specifications of the stochastic process for productivity and of preferences. First, to capture sustained periods of rapid (stagnant) productivity growth, log TFP growth γ^a has the following stochastic process:

$$\begin{aligned}\gamma_t^a &= \gamma_t^t + z_t - z_{t-1} \\ z_t &= \rho_z z_{t-1} + \varepsilon_{z,t}, \text{ where } \varepsilon_z \sim \text{i.i.d. } N(0, \sigma_z^2) \\ \gamma_t^t &= \varepsilon_{\gamma,t} \sim \text{i.i.d. } \Gamma(\mu_\gamma, \sigma_\gamma^2) \text{ with probability } P \\ &\quad \gamma_{t-1}^t \text{ with probability } 1 - P,\end{aligned}\tag{12}$$

where γ_t^t is the stochastic (log) growth rate of trend productivity T_t , z_t reflects transitory shocks, and the distribution $\Gamma(\mu_\gamma, \sigma_\gamma^2)$ is a truncated normal distribution with mean μ_γ and variance σ_γ^2 . The shocks to the trend growth rate are occasional but persistent, whereas the transitory shocks occur every period.

Second, for preferences I consider specifications of the momentary utility function (equation (3)) that allow the living standard X_t to impact agents’ decisions. This requires $\eta < 1$. Following Abel (1999), the living standard is a function of productivity and recent levels of consumption per capita. Specifically,

$$X_t = C_{t-1}^{\phi_1} T_t^{1-\phi_1}\tag{13}$$

where $0 \leq \phi_1 \leq 1$. The special case with $\phi_1 = 1$ corresponds to the “catching up with the Joneses” formulation in Abel (1990). The living standard is a function of T_t for a couple of reasons. First, a stochastic trend T_t is used rather than a constantly growing trend, say μ_γ^t , because it seems reasonable that the standard of living in a country may grow faster at some times and slower at others. Second, T_t is used rather than total productivity A_t to capture the idea that changes in the living standard depend on permanent changes in productivity.

Finally, including trend productivity in addition to lagged consumption is a reduced-form way of capturing a forward-looking aspect of the living standard.

The state space for this model specification is $S_t = \{\widehat{K}_t, \gamma_t^t, z_t, \gamma_t^X, \widehat{A}_t, \widehat{C}_{t-1}\}$. The current values of both the transitory shock to productivity z_t and the trend growth rate of productivity γ_t^t are needed to form expectations of future productivity growth. In general, the final three state variables are all necessary for forming expectations of future growth of the living standard γ_{t+1}^X , although for some parameterizations (e.g., $\phi_1 = 0$), a subset of these variables is sufficient.

5.1.1 Choosing Parameter Values

Many of the parameters are set as they were for the textbook RBC specification (see Section 4.1), while others, namely η and σ , which were previously pinned down by functional-form assumptions, can now be chosen based on estimates from the labor supply literature. To choose the productivity process parameters, I use techniques for estimating parameters of state-space models with regime switches. Finally, I investigate the implications of various functional forms for the living standard by considering various values for ϕ_1 .

Preference Parameters The first-order condition for labor input (equation 5) takes the form

$$bN_t^\nu C_t^\eta X_t^{(1-\eta)} = (1 - \tau_N) W_t,$$

which can be written, dropping constant terms, as

$$n_t = \frac{w_t - \eta c_t - (1 - \eta) x_t}{\nu}$$

or

$$n_t = \frac{1}{\nu} \widehat{w}_t - \frac{\eta}{\nu} \widehat{c}_t. \tag{14}$$

Recall that lowercase letters denote logged variables and a “hat” denotes the variable has been normalized by X_t ; that is, $\widehat{c} = \ln(\frac{C}{X})$. From equation (14), one sees that η would govern the relative magnitude of the income elasticity of labor supply to the compensated wage elasticity in a static labor supply context. Tables 1 and 2 of Blundell and MaCurdy (1999) report estimates of the uncompensated wage elasticity and income elasticity from a number of studies, and thus, one can infer the compensated wage elasticity. The income elasticity is typically substantially smaller in magnitude than the compensated wage elasticity, although its relative magnitude varies. η is set to 0.33 in the baseline model, and I will illustrate how alternative values affect the results. $\sigma = 1$ implies a steady-state elasticity of intertemporal substitution of 0.64, within the range of estimates from the literature.

In the baseline model, $\phi_1 = 0$ so that the living standard is only a function of trend productivity. I will also consider a “catching up with the Joneses” living standard, $\phi_1 = 1$, and living standards that depend on both lagged consumption and trend productivity, $0 < \phi_1 < 1$.

Productivity Parameters The parameters for the productivity distribution are obtained by maximum likelihood estimation. A description of the estimator taken from Kim and Nelson (1999) is provided in the technical appendix. The estimates include $\mu_\gamma = 1.0052$ and $\sigma_\gamma = 0.0022$. These values imply a long-run growth rate of per-capita output of 2.1 per year, and because the distribution for γ^t is truncated at ± 3 standard deviations, a trend growth rate that is bounded between -0.6% and 4.8% per year. The parameters for the Z process, $\rho_z = 0.88$ and $\sigma_z = 0.0099$, imply less unconditional variance of the cyclical shock than in the textbook RBC model. Finally, the estimate for P implies that the trend growth of productivity changes, on average, once every 70 quarters.

The parameters for the baseline “living standard” model are given in Table 7.

5.1.2 Results

I once again conduct the two experiments described in Section 4.1. Tables 8 and 9 report average moments of high and lower-frequency fluctuations from 200 model simulations. The baseline “living standard” specification performs noticeably better than the textbook RBC model. Although the correlation between hours worked and output/TFP at lower frequencies is not negative, the difference from high to lower frequencies is substantial. The correlation between TFP and hours worked drops by 0.80 when moving from high to lower frequencies (slightly larger than the change in the data), while $Corr(Y, N)$ drops by 0.64 (less than the change in the data but sizable). That these correlations are still positive at the lower frequencies reflects the fact that I only consider shocks to TFP. Other researchers have included a wide variety of alternative shocks (government spending, monetary shocks, etc.) within the DSGE framework. Adding such realistic shocks would reduce the correlations between TFP and other variables at all frequencies.

The choice of a simple model was made to most clearly illustrate the effects of the living standard. Given this modelling decision, there are clear discrepancies between the moments produced by the model and the data. Some of these can be fixed by considering alternative values for parameters. For example, a higher elasticity of the labor supply ($\frac{1}{\nu}$) would make labor input more volatile [Hansen (1985), Rogerson (1988)]. Other discrepancies, like the

decrease in the correlation of TFP and output from high to lower frequencies, could be fixed by considering a richer model with more shocks.

The second experiment of simulating the model with the actual U.S. Solow residual as the driving force is more complicated than it was for the textbook RBC model, because it now requires a decomposition of productivity growth into trend and transitory components. Alternative decompositions will change the model's predictions through two channels: the living standard and agents' expectations. Because only the trend (and not the transitory) part of productivity growth enters the living standard, any decomposition is an assumption about how the living standard evolved over the postwar period. As for expectations, the higher the trend component, the higher is the expected level of future productivity.

To illustrate how the living standard model works, I show the simulation results for the case of one change in trend productivity growth. I use Bai and Perron's (1998) methods for identifying trend breaks in univariate time series to provide discipline for the decomposition. At the 10% confidence level, the hypothesis that no trend breaks occurred in the productivity growth series can be rejected in favor of the alternative hypothesis that one break occurred. Moreover, these tests identify the date of the break as the second quarter of 1966. Given the break date, I construct the series for the trend and transitory components (γ^T and z) in a way that imposes orthogonality between the two series (to be consistent with the assumptions on the stochastic processes) and minimizes the sum of the squared transitory shocks. Details are provided in the technical appendix.¹⁸

Figure 9 displays the lower frequencies of the TFP series along with the hours worked and output series from the model and the data. The hours worked series generated by the model is roughly similar to the actual series as the 50s and 90s are times of relatively high labor input. The one major discrepancy between the series is the increase in simulated hours worked during the late 60s and early 70s. The effect of this increase in hours worked can also be seen in the simulated output series in the bottom panel of Figure 9. This discrepancy could be reduced in a couple of ways. The first is by adding more shocks to the model. Figure 10 shows the impact of adding distortionary labor income taxes, which counteract some of the increase in

¹⁸I thank John Fernald and his research assistant, Andrew McCallum, for running the Bai-Perron statistical tests on my TFP series. It is difficult to make the case one particular decomposition of productivity growth over another. Although I report the results of my model simulations for the case of one break, note that these tests can be used to check for an arbitrary number of breaks. In fact, the hypothesis of no breaks was rejected in favor of the alternatives of 3 or 4 breaks as well. Moreover, even conditioning on the number of breaks, Fernald (2005) explains that there is considerable uncertainty about the exact break dates. Thus, this experiment should be seen as illustrating the effects of a plausible living standard, rather than literally arguing for a living standard that grew at one rate before 1966:2 and at another rate afterwards.

hours worked during the late 60s.

The second way to improve the model’s fit would be to consider the impacts of learning in the model. Figure 9 displays hours worked from a simulation in which individuals perfectly recognize a downward shift in the trend rate of productivity in the second quarter of 1966. The impact of such a drop is for hours worked to increase due to the negative effect on permanent income of lower expected future productivity growth. As shown by Edge, Laubach, and Williams (2004), if individuals instead attributed part of this drop in productivity to temporary shocks, they would not have as much of an incentive to increase hours worked. The technical appendix (8.4) discusses some details for adding learning (i.e., signal extraction) to the model, although results of this exercise are not yet available.

To understand the model’s ability to capture the decrease in hours worked at times of fast TFP growth and the importance of the living standard for driving this result, it is useful to consider the response of hours to a permanent shock to the trend growth rate of productivity γ^g . Figure 11 displays the response of hours worked to a one-standard-deviation increase in γ^g for different values of the income elasticity η . For the baseline living standard model ($\eta = 0.33$), hours worked decline in the initial period and continue to decline as the economy transitions to a new steady-state. Thus, hours worked can have an extended decline while output and TFP grow at a fast rate. For a model without a living standard ($\eta = 1$), the initial response of hours is greater due to the stronger income effect, but in the long-run, hours worked actually increase.¹⁹ Thus, without a living standard, a prolonged decrease in hours worked could only be generated by many positive shocks to γ^t arriving in succession. Not only would a string of successive shocks cause consumption to increase more rapidly than output (as discussed in Section 4.3), it would also make hours worked negatively correlated with productivity at high frequencies.

In contrast, the living standard model can generate the positive high-frequency correlation between hours worked and TFP/output at the same time as it provides a force for the negative correlation at lower frequencies. Consider the intratemporal equilibrium condition

$$n_t = \frac{w_t - \eta c_t - (1 - \eta) x_t}{\nu} = \frac{(\eta - \alpha)t_t + (1 - \alpha)z_t + \alpha k_t - \eta c_t}{\nu + \alpha}, \quad (15)$$

¹⁹I considered a version of the model with the trend-break productivity process but no living standard ($\eta = 1$). The results of simulating the model with actual Solow residuals as the driving force are very similar to the “catching up with the Joneses” model shown in Figure 12. In comparison to the living standard model, hours worked do not decline as much in the 50s or increase as quickly in the 90s. Moreover, the break in trend productivity growth in the second quarter of 1966 causes a stronger increase in labor input. For the monte-carlo exercise, the correlation between hours worked and output (TFP) only drops by 0.27 (0.19) when moving from high to lower frequencies.

where the second equality follows from $w = MPL$ and $x = t$. The transitory (z) shocks will drive much of the high-frequency correlation but will be less important at the lower frequencies because of their temporary nature. This equation also provides another way of framing the discussion of the previous paragraph. Abstracting from temporary shocks to productivity ($z = 0$), log effective units of capital ($k - t$) are more responsive to a change in the growth rate of productivity γ^t than are log effective units of consumption ($c - t$). (This must be true in order for long-run hours worked to decline when $\eta = \alpha = 0.33$.) For smaller values of η , the long-run decline in hours worked associated with an increase in the growth rate of productivity will be even greater.

5.2 Alternative “Living Standard” Formulations

The living standard in the baseline specification of the model is simply the trend part of productivity:

$$x_\tau = t_\tau = \sum_{s=1}^{\tau} \gamma_s^t,$$

but alternative formulations of the living standard can also be considered. This is useful for comparing the model to other habit formation models in the business cycle literature and for demonstrating the key features of the living standard for explaining the lower-frequency puzzle. I first describe various alternatives and then present some summary statistics from simulations of these models.

By setting $\phi_1 = 1$, the living standard is fully backwards-looking, a function only of lagged aggregate consumption:

$$x_\tau = c_{\tau-1}.$$

This is the “catching up with the Joneses” specification considered by Abel (1990). More generally, the living standard could be a weighted average of trend growth and past levels of consumption, with ϕ_1 denoting the relative weight of lagged consumption:

$$x_\tau = \phi_1 c_{\tau-1} + (1 - \phi_1) \sum_{s=1}^{\tau} \gamma_s^t.$$

To capture the idea that individuals may overreact, becoming very optimistic (pessimistic) during times of fast (slow) growth, I allow the living standard to increase more rapidly than the trend growth of TFP during prosperous times and to not grow as quickly during times of relative stagnation. This is done by setting the parameter $\lambda > 1$ for the living standard specification

$$x_\tau = \lambda \sum_{s=1}^{\tau} (\gamma_s^t) + \tau (1 - \lambda) \ln(\mu_\gamma).$$

Note that $\lambda = 1$ delivers the baseline version of the living standard, while $\lambda = 0$ implies a constantly growing living standard.²⁰

Table 10 reports the *difference* between the average correlation of hours worked with output and TFP at high and lower frequencies for these various formulations of the living standard. The formulations produce similar high-frequency correlations of around 0.90, but the correlations generated at lower-frequencies are quite different. Living standards which grow (on average) at least as quickly (slowly) as productivity during extended periods of fast (slow) productivity growth are best able to generate the drop in the correlation at lower frequencies.

Figure 12 shows the lower-frequency fluctuations in the hours worked series that result from using the actual Solow residuals as the driving force for each of these specifications. The specifications with living standards that are mostly a function of the stochastic trend of productivity (i.e., “baseline” and “over-reaction”) do best at replicating the movement in hours worked seen in the data. The key is that the “true” MRS, $bN_t^\nu C_t^\eta X_t^{(1-\eta)}$, grows quickly at times of fast productivity growth. Note that when the living standard simply grows at a constant rate, the model performs more poorly than the textbook RBC model because the income effect is smaller in the living standard model ($\eta = 0.33$) and the wedge in the MRS (X) does not grow quickly.

5.3 Alternative Interpretations of the Model

The model considered above takes changes in productivity as the exogenous driving force of the economy and specifies that persistent changes in productivity enter into a living standard.

²⁰Another formulation for the living standard is one that is forward-looking, depending on expectations of future productivity. It could take the form

$$x_\tau = E_\tau \left\{ \frac{a_{\tau+j}}{(1-\alpha)} \right\} - j \ln(\mu_\gamma)$$

where $E_t(a_{\tau+j})$ is the expected productivity level j periods in the future and the other terms are simply for scaling purposes. The living standard could then be expressed as

$$x_\tau = t_\tau + f_1(j, P, \gamma_\tau^t - \ln(\mu_\gamma)) + f_2(j, \rho_z, z_\tau)$$

where f_1 is an increasing function of j , P , and the trend growth rate γ_τ^t , and f_2 goes to 0 as j grows. For j sufficiently large, the transitory shock has little weight in the living standard. This forward-looking specification is similar to the baseline specification, $x_\tau = g_\tau$, although changes in the trend growth rate have an additional impact through f_1 .

Individuals derive utility not just from the absolute levels of goods and leisure they consume, but from these levels relative to the standard. Importantly, an increase in the living standard increases the MRS between consumption and leisure. The high average productivity (wage) growth in the 50s and 60s is thus seen as driving the contemporaneous increase in leisure time, while the slow productivity growth in the last quarter of the 20th century is interpreted as a factor that led to increased market work through the 80s and 90s. As discussed before, the usual income effect of a wage change on labor supply is not strong enough to generate these patterns, and thus, a living standard explanation is proposed.

Other macroeconomic models share the mathematical structure of the living standard model, including models with (external) habits and various forms of non-market production, but there are reasons why I have chosen to interpret the state variable in preferences as a living standard. First, the distinction between a living standard and an external habit is slight but important. The main difference is that the living standard depends on growth in productivity (which is closely tied to income and wages) and not solely on lagged consumption. The idea of using trend productivity was to capture the idea that there may be a forward-looking aspect of agents' reference level (see Footnote 20). As shown in the previous subsection, allowing for productivity in the reference level, and not solely lagged consumption, is critical for the model's performance.

A leisure-enhancing production interpretation of the model is similar to the living standard interpretation, although the mechanism that drives the increased desire for leisure in prosperous times is different [Greenwood and Vandenberg (2005), Kopecky (2005)]. The increased desire for leisure would result from an increase in the consumption of goods that are complements of leisure time. Examples of such goods include books, radios, televisions, admissions to concerts, and travel. In periods of rapid growth, declines in the relative price of leisure goods could explain the negative correlation between hours worked and output/TFP.

Figure 13 plots the relative price of a basket of leisure goods over the postwar period, as constructed by Kopecky (2005).²¹ Periods of fast (slow) productivity growth do not appear to coincide with drops (increases) in this measure of the relative price of leisure goods, making this explanation less appealing than the living standard explanation. There is, however, an important caveat. The measure of the relative price in Figure 13 does not correct for changes in quality or the variety of leisure goods. If, for example, improvements in the quality of leisure goods are greater than those for the average good in the CPI basket at times of fast productivity growth, a corrected relative price series could display the movements needed for this explanation to work. Pursuing these corrections is left for future research.

²¹I thank Karen Kopecky for making this data available.

Home production provides yet another interpretation of the state variable in preferences that plays such an important role in the “living standard” model. If the consumption of home-produced goods increase rapidly during times of fast market productivity growth, the marginal utility of consumption can be low enough to rationalize the contemporaneous decrease in market hours worked. In this interpretation, the 50s and 60s were times when individuals consumption of non-market goods grew rapidly, either because they spent more time in homework or because the productivity of homework grew rapidly. Figure 14 shows an estimate of the number of annual hours per capita spent in homework over the postwar period, as constructed by Ramey and Francis (2005).²² Since homework apparently decreased over the first few decades of the sample period, the home production story would require that home productivity grew extremely fast in this period, much faster than market productivity. It is, of course, possible that home productivity does grow faster than market productivity during times of fast market productivity growth, although one may think that new technologies first impact the market sector before diffusing to the non-market sector.

6 Conclusion

Long-run economic growth and business cycles have been two of the most active areas of macroeconomic research. This paper has focused on the often overlooked gap in between, lower-frequency fluctuations. One striking fact in U.S. postwar data is that hours worked per capita is negatively correlated with both output per capita and TFP at lower frequencies, while these variables are positively correlated at high frequencies. The hypothesis proposed herein is that extended periods of above average growth in productivity lead to rapid output growth and decreases in hours worked, while temporary increases in productivity lead to temporary increases in both output and hours worked. The mechanism that delivers the lower-frequency behavior in a DSGE model is a “living standard” that changes smoothly over time, growing quickly (sluggishly) in times of fast (slow) average productivity growth.

An explanation that relies on unobserved changes in preferences is admittedly unsatisfactory in the sense that one would like to find *measurable* economic variables that can explain the lower-frequency fluctuations. Thus, instead of viewing this paper as evidence of the importance of a “living standard”, it can alternatively be seen as (i) a demonstration that some explanations (i.e., taxes or various expectations of future growth) will not work and (ii) a preliminary step for finding explanations that will. The next step could include moving outside of the representative agent framework to consider important forms of heterogeneity, like

²²I thank Valerie Ramey and Neville Francis for sharing their data.

the changing demographic composition of the population. Since individuals of, say, different age arguably have different preferences, such a model may provide an understanding of the apparent preference shift.

Other directions in which future work on this topic is likely to proceed include: (i) extending the model to include learning about trend breaks in productivity growth, which may improve the model's performance around breaks and could also be relevant for thinking about other interesting patterns in the data, such as asset-pricing puzzles; and (ii) considering other lower-frequency patterns, including the tremendous medium-run variation seen in cross-country growth experience.

7 Data Appendix

7.1 Variable Definitions

The following two tables contain the baseline and alternative variable definitions considered in Section 2. All data series were converted from nominal to real units using the GDP deflator.

Baseline Variable Definitions	
Variable	Measure
Output (Y)	Gross Domestic Product
Consumption (C)	Personal Consumption Expenditures
Investment (I)	Gross Private Domestic Invest. (Fixed + Inventories)
Hours Worked (N)	Hours of all persons (Business Sector)
Capital (K)	Net Stock of Private Produced Assets (Fixed + Inv.)
TFP (A)	$A = Y/(K^{0.333}N^{0.667})$
Labor Productivity (Y/N)	Y/N
Return to Capital (r)	Capital Share of Income Multiplied by Output to Capital Stock Ratio minus the Depreciation Rate

Alternative (Broader) Data Definitions	
Variable	Measure
Output (Y)	GDP + Flow of Services from Cons. Durables Flow of Services from Govt. Capital Stock
Consumption (C)	Consumption of Nondurables, Services, and Flow of Services from Consumer Durables
Investment (I)	GPDI (Fixed + Inv.) + Cons. Dur. + Govt. Invest.
Hours Worked (N)	Hours of all persons (Domestic)
Capital (K)	Net Stock of Private Produced Assets (Fixed + Inv.) + Cons. Durables + Govt. Fixed Assets
TFP (A)	$A = Y/(K^{0.333}N^{0.667})$
Labor Productivity (Y/N)	Y/N
Return to Capital (r)	Capital Share of Income Multiplied by Output to Capital Stock Ratio minus the Depreciation Rate
Govt Spending (G)	Govt. Cons. + Service Flows from Govt. Capital

7.3 Constructing Quarterly Variables from Annual Data

The quarterly capital stock is constructed as follows: the private capital stock in the first quarter of each year is taken from NIPA Table 5.9 and converted to real terms using the GDP deflator. Gross private fixed investment and private consumption of fixed capital (both in real terms at quarterly rates) are used to construct the capital stock for quarters 2-4 and quarter 1 of the next year. The discrepancy between the constructed quarter 1 capital stock and the quarter 1 capital stock taken from Table 5.9 is then equally divided between the 4 quarters of the previous year.

A similar method is used for the construction of quarterly government fixed assets and the stock of consumer durables. The service flows from these stocks are then calculated following Cooley and Prescott (1995).

The measure of domestic hours worked is constructed by scaling the quarterly private hours worked (LBMN series) by the annual ratio of domestic to private hours found in NIPA Table 6.9.

The (net) return to capital is capital's share of income multiplied by the ratio of output to the capital stock minus the depreciation rate ($\alpha \frac{Y}{K} - \delta$). Capital's share of income is constructed as

$$\alpha = \frac{\text{Priv net oper surp} + \text{Cons of fix cap} - \text{Proprietor's inc.} - \text{Bus. trans. pmts}}{\text{GDI} - \text{Proprietor's income} - \text{Business transfer pmts}}.$$

8 Technical Appendix

Throughout this appendix, any notation not explicitly defined is consistent with the notation used in the rest of the paper.

8.1 Solution Method

To solve the model, I use a policy-function iteration approach (for example, see sections 17.5-17.9 of Judd (1998)) that operates directly on the necessary and sufficient conditions for an equilibrium. In theory, the equilibrium can be described as functions, $\widehat{C}(s)$, $N(s)$, $\widehat{K}(s)$, that satisfy the equilibrium conditions, equations (4)-(6), at all points in the state space, $s \in S$. Policy-function iteration is implicitly defined by

$$1 = \beta E \left\{ \frac{h(\gamma^{X^+}) u_C(\widehat{C}^j(s^+), N^j(s^+))}{\gamma^{X^+} u_C(\widehat{C}^{j+1}(s), N^{j+1}(s))} \left[(\widehat{A}^+)^{1-\alpha} F_K(\widehat{K}^+, N^j(s^+)) + 1 - \delta \right] \right\},$$

$$-\frac{u_N(\widehat{C}^{j+1}(s), N^{j+1}(s))}{u_C(\widehat{C}^{j+1}(s), N^{j+1}(s))} = \widehat{A}^{1-\alpha} F_N(\widehat{K}, N^{j+1}(s)),$$

$$\widehat{C}^{j+1}(s) + \widehat{K}^{j+1}(s) - (1 - \delta)\widehat{K} + \widehat{G} = \widehat{A}^{1-\alpha} F(\widehat{K}, N^{j+1}(s)).$$

Given the functions \widehat{C}^j , N^j , \widehat{K}^j and some $s \equiv (\widehat{K}, z, \gamma^T, \widehat{A}, \gamma^X, \widehat{G})$, I solve for the values of $\widehat{C}^{j+1}(s)$, $N^{j+1}(s)$, $\widehat{K}^{j+1}(s)$ that solve the above system; since this can be done for each s , I have the functions \widehat{C}^{j+1} , N^{j+1} , \widehat{K}^{j+1} . The procedure is repeated until convergence.

To implement this procedure on the computer, one needs to choose how to approximate the policy functions and how to approximate the expectation in the intertemporal euler equation. Because the state space is multi-dimensional, approximating the policy function could require solving the equilibrium conditions at a large number of points in the state space. Fortunately, Smolyak's algorithm provides an efficient way of approximating smooth multivariate functions. The algorithm consists of both a specification of the grid of points, $\mathcal{H} \in S$, at which to solve for the policy functions and the procedure for interpolating between these points. I use complete polynomials of degree 4 to approximate the equilibrium. For a more detailed description of Smolyak's method, please see Krueger and Kubler (2004), especially sections 3.3 - 3.5. For approximating the expectation in the intertemporal euler equation, I use the appropriate quadrature formulas from chapter 7 of Judd (1998).

To assess the quality of the solution, I compute relative Euler equation errors as in Judd (1992). For each of the three equilibrium conditions, I compute

$$err_t = \left| \frac{(\text{Right-Hand Side})_t}{(\text{Left-Hand Side})_t} - 1 \right|.$$

I simulate the economy for 10,000 periods and record the maximal and average error along the simulated path. For the intertemporal euler equation and resource constraint, the maximal error is typically on the order of 10^{-3} and the average error on the order of 10^{-4} . The intratemporal euler equation can actually be solved exactly for $N(s)$ given the solution for $\widehat{C}(s)$ and $\widehat{K}(s)$. Thus, by construction, the error for this equation is 0.

8.2 Markov Chain for Persistent Shocks

In order to facilitate the choice of parameters (discussed in the next subsection) and to allow for a ‘learning’ extension of the model, the stochastic process for trend productivity growth γ^T in the “living standard” model is characterized by the following time-invariant Markov chain:

$$\bar{\gamma} = \begin{bmatrix} \bar{\gamma}^1 \\ \vdots \\ \bar{\gamma}^M \end{bmatrix}, \quad \pi_\gamma = \begin{bmatrix} \pi_\gamma^1 \\ \vdots \\ \pi_\gamma^M \end{bmatrix}$$

$$p = \begin{bmatrix} 1 - P & \frac{P\pi_\gamma^2}{1-\pi_\gamma^1} & \cdots & \frac{P\pi_\gamma^M}{1-\pi_\gamma^1} \\ \frac{P\pi_\gamma^1}{1-\pi_\gamma^2} & 1 - P & & \\ \vdots & & \ddots & \\ \frac{P\pi_\gamma^1}{1-\pi_\gamma^M} & & & 1 - P \end{bmatrix}$$

where $\bar{\gamma} \in R^M$ records the possible values for γ^T , π_γ records the unconditional probability of being in each state, and p is a transition matrix which records the probabilities of moving from one value of γ^T to another in one period. $\bar{\gamma}$ and π_γ are chosen so that the distribution from which trend productivity growth is drawn has approximately a normal distribution with mean μ_γ and variance σ_γ^2 . Following Tauchen (1986),

$$\bar{\gamma}^m = \mu_\gamma + \left(\frac{2(m-1)}{M-1} - 1 \right) * Trunc * \sigma_\gamma, \quad m = 1, \dots, M.$$

$Trunc = 3$ and $M = 13$ for all specifications of the model. Thus, there are 13 possible values for γ^T that are equispaced over the interval $[\mu_\gamma - 3\sigma_\gamma, \mu_\gamma + 3\sigma_\gamma]$. Let $w = \bar{\gamma}^m - \bar{\gamma}^{m-1}$ and

$\Phi(\cdot)$ be the standard normal cumulative distribution function. Then, if m is between 2 and $M - 1$, set

$$\pi_\gamma^m = \Phi\left(\frac{\bar{\gamma}^m - \mu_\gamma + w/2}{\sigma_\gamma}\right) - \Phi\left(\frac{\bar{\gamma}^m - \mu_\gamma - w/2}{\sigma_\gamma}\right),$$

otherwise,

$$\pi_\gamma^1 = \Phi\left(\frac{\bar{\gamma}^1 - \mu_\gamma + w/2}{\sigma_\gamma}\right) \text{ and } \pi_\gamma^M = 1 - \Phi\left(\frac{\bar{\gamma}^M - \mu_\gamma - w/2}{\sigma_\gamma}\right).$$

8.3 Estimating Parameters of Persistent Shock Process

To estimate the parameters of the productivity process of the “living standard” model, I use the maximum likelihood estimation procedure described by Kim and Nelson (1999), which is a summary of the methods developed in Kim (1994). I first represent the productivity process in state-space form, then describe the Kim filter (an extended version of the Kalman filter that allows for regime switches), and finally detail the approximate maximum likelihood estimation of the parameters of the productivity process.

8.3.1 State-Space Form

The productivity process can be represented as a state-space model with regime switching. There are M regimes: one for each possible value of γ^T .

Letting $\gamma_t^A = \ln\left(\frac{A_t}{A_{t-1}}\right)$, a state-space representation of the growth rate of TFP can be written compactly in the form:

$$\begin{aligned} \text{Measurement Equation:} \quad & \gamma_t^A = \mathbf{x}' \mathbf{a}_t + B_{S_t} \\ \text{Transition Equation:} \quad & \mathbf{a}_t = \mathbf{T} \mathbf{a}_{t-1} + \mathbf{R} \eta_t \\ \text{Shocks:} \quad & \eta_t \sim N(0, Q) \end{aligned}$$

with

$$\begin{aligned} \mathbf{a}_t &= \begin{bmatrix} z_t \\ z_{t-1} \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} 1 \\ -1 \end{bmatrix} \\ \mathbf{B}_{S_t} &= \ln(\bar{\gamma}_{S_t}) \text{ for } S_t = 1, \dots, M \\ \mathbf{T} &= \begin{bmatrix} \rho_z & 0 \\ 1 & 0 \end{bmatrix}, \quad \mathbf{R} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \text{ and } \eta = \varepsilon_z. \end{aligned}$$

The variance-covariance matrix of the underlying shocks is

$$Q = \sigma_z^2.$$

Transition probabilities for the Markov-switching variable S_t are given by

$$p \equiv \begin{bmatrix} p_{11} & p_{12} & \cdots & p_{1M} \\ p_{21} & & & \\ \vdots & & \ddots & \\ p_{M1} & & & p_{MM} \end{bmatrix} = \begin{bmatrix} 1 - P & \frac{P\pi_\gamma^2}{1-\pi_\gamma^1} & \cdots & \frac{P\pi_\gamma^M}{1-\pi_\gamma^1} \\ \frac{P\pi_\gamma^1}{1-\pi_\gamma^2} & 1 - P & & \\ \vdots & & \ddots & \\ \frac{P\pi_\gamma^1}{1-\pi_\gamma^M} & & & 1 - P \end{bmatrix}$$

where $p_{ij} = \Pr[S_t = j | S_{t-1} = i]$.

8.3.2 Kim's (1994) Filter for State-Space Models with Markov-Switching (Kim and Nelson, Section 5.2)

The filter for the state-space model with Markov switching is a combination of extended versions of the Kalman filter and the Hamilton filter, along with appropriate approximations. Here I describe the filter for the state-space representation discussed above.

First, I will define some notation. Let ψ_{t-1} denote the vector of observations available as of time $t - 1$, $\psi_{t-1} = \{\gamma_1^A, \dots, \gamma_{t-1}^A\}$. The goal is to form a forecast of the unobserved state vector \mathbf{a}_t based not just on ψ_{t-1} but also conditional on the random variable S_t taking on the value j and on S_{t-1} taking on the value i :

$$\mathbf{a}_{t|t-1}^{(i,j)} = E[\mathbf{a}_t | \psi_{t-1}, S_t = j, S_{t-1} = i].$$

The proposed algorithm calculates a battery of M^2 such forecasts for each date t , corresponding to every possible value for i and j . Associated with these forecasts are M^2 different mean squared error matrices:

$$\mathbf{P}_{t|t-1}^{(i,j)} = E[(\mathbf{a}_t - \mathbf{a}_{t|t-1})(\mathbf{a}_t - \mathbf{a}_{t|t-1})' | \psi_{t-1}, S_t = j, S_{t-1} = i].$$

The key part of the algorithm is to reduce the $(M \times M)$ posteriors $(\mathbf{a}_{t|t}^{(i,j)}$ and $\mathbf{P}_{t|t}^{(i,j)})$ into M posteriors $(\mathbf{a}_{t|t}^j$ and $\mathbf{P}_{t|t}^j)$ to complete the Kalman filter described below. Kim's (1994) filter contains the following steps:

1. Run the Kalman filter given in equations (16)-(21) for $i, j = 1, 2, \dots, M$.

$$\mathbf{a}_{t|t-1}^{(i,j)} = \mathbf{T}\mathbf{a}_{t-1|t-1}^i \quad (16)$$

$$\mathbf{P}_{t|t-1}^{(i,j)} = \mathbf{T}\mathbf{P}_{t-1|t-1}^i\mathbf{T}' + \mathbf{R}\mathbf{Q}\mathbf{R}' \quad (17)$$

$$v_{t|t-1}^{(i,j)} = \gamma_t^A - \mathbf{x}'_{t|t-1}\mathbf{a}_{t|t-1}^{(i,j)} - B_j \quad (18)$$

$$f_{t|t-1}^{(i,j)} = \mathbf{x}'_{t|t-1}\mathbf{P}_{t|t-1}^{(i,j)}\mathbf{x} \quad (19)$$

$$\mathbf{a}_{t|t}^{(i,j)} = \mathbf{a}_{t|t-1}^{(i,j)} + \mathbf{P}_{t|t-1}^{(i,j)}\mathbf{x}[f_{t|t-1}^{(i,j)}]^{-1}v_{t|t-1}^{(i,j)} \quad (20)$$

$$P_{t|t}^{(i,j)} = (\mathbf{I} - \mathbf{P}_{t|t-1}^{(i,j)}\mathbf{x}[f_{t|t-1}^{(i,j)}]^{-1}\mathbf{x}')\mathbf{P}_{t|t-1}^{(i,j)} \quad (21)$$

2. Calculate $\Pr[S_t, S_{t-1}|\psi_t]$ and $\Pr[S_t|\psi_t]$, for $i, j = 1, 2, \dots, M$.

$$\begin{aligned} \Pr[S_t = j, S_{t-1} = i|\psi_{t-1}] &= \Pr[S_t = j|S_{t-1} = i] * \Pr[S_{t-1} = i|\psi_{t-1}] \\ f(\gamma_t^A|S_{t-1} = i, S_t = j, \psi_{t-1}) &= \frac{\exp\left\{-\frac{1}{2}v_{t|t-1}^{(i,j)'}\left(f_{t|t-1}^{(i,j)}\right)^{-1}v_{t|t-1}^{(i,j)}\right\}}{(2\pi)^{\frac{N}{2}}|f_{t|t-1}^{(i,j)}|^{\frac{1}{2}}} \\ f(\gamma_t^A, S_{t-1} = i, S_t = j|\psi_{t-1}) &= f(\gamma_t^A|S_{t-1} = i, S_t = j, \psi_{t-1}) * \\ &\Pr[S_t = j, S_{t-1} = i|\psi_{t-1}] \\ f(\gamma_t^A|\psi_{t-1}) &= \sum_{j=1}^M \sum_{i=1}^M f(\gamma_t^A, S_{t-1} = i, S_t = j|\psi_{t-1}) \quad (22) \\ \Pr[S_t = j, S_{t-1} = i|\psi_t] &= \frac{f(\gamma_t^A, S_{t-1} = i, S_t = j|\psi_{t-1})}{f(y_t|\psi_{t-1})} \\ \Pr[S_t = j|\psi_t] &= \sum_{i=1}^M \Pr[S_t = j, S_{t-1} = i|\psi_t] \end{aligned}$$

3. Using these probability terms, collapse $M \times M$ posteriors in (20) and (21) into $M \times 1$ using the following equations:

$$\begin{aligned} \mathbf{a}_{t|t}^j &= \frac{\sum_{i=1}^M \Pr[S_t = j, S_{t-1} = i|\psi_t]\mathbf{a}_{t|t}^{(i,j)}}{\Pr[S_t = j|\psi_t]} \\ \mathbf{P}_{t|t}^j &= \frac{\sum_{i=1}^M \Pr[S_t = j, S_{t-1} = i|\psi_t] \left\{ \mathbf{P}_{t|t}^{(i,j)} + \left(\mathbf{a}_{t|t}^j - \mathbf{a}_{t|t}^{(i,j)}\right) \left(\mathbf{a}_{t|t}^j - \mathbf{a}_{t|t}^{(i,j)}\right)'\right\}}{\Pr[S_t = j|\psi_t]} \end{aligned}$$

4. To start the filter, the following initial values are needed:

$$\begin{aligned} \mathbf{a}_{0|0}^j &= \mathbf{0} \\ \text{vec}\left(\mathbf{P}_{0|0}^j\right) &= (\mathbf{I} - \mathbf{T} \otimes \mathbf{T})^{-1}\text{vec}(\mathbf{R}\mathbf{Q}) \\ \Pr(S_0 = j) &= \pi_\gamma^j \end{aligned}$$

Note that $\text{vec}(\mathbf{RQ})$ is not conformable to the other matrices. For this step, in a slight abuse of notation, let \mathbf{R} and \mathbf{Q} be 2×2 matrices, where the last column of \mathbf{R} and last row and last column of \mathbf{Q} are zeros.

8.3.3 Approximate Maximum Likelihood Estimation

The filter computes the density of γ_t^A conditional on past information, $f(\gamma_t^A|\psi_{t-1})$, $t = 1, 2, \dots, T$, from equation (22). The approximate log likelihood function is given by

$$LL = \ln [f(\gamma_1^A, \dots, \gamma_T^A)] = \sum_{t=1}^T \ln [f(\gamma_t^A|\psi_{t-1})]. \quad (23)$$

To estimate the parameters of the model, I use a nonlinear optimization procedure to maximize (23) with respect to the underlying unknown parameters, $\{\rho_z, \sigma_z, \mu_\gamma, \sigma_\gamma, P\}$.

8.4 Decomposing TFP into Trend and Cyclical Components

8.4.1 Bai-Perron

For a model with both persistent and transitory shocks to productivity growth, feeding the actual U.S. Solow residuals through the model requires a decomposition of productivity growth into the two components. Bai and Perron's (1998) methods for identifying trend breaks in univariate time series are used to identify break dates. Let B be the number of breaks and τ_1, \dots, τ_B denote the dates of the breaks.

Given the logged Solow residuals (a_τ) and the break dates $\{\tau_1, \dots, \tau_B\}$, I construct the series $\{\gamma_\tau^t\}$ and $\{z_\tau\}$ by running the following OLS regression with serially correlated errors:

$$a_\tau = \varsigma + [\Gamma_1 D_1 + \dots + \Gamma_{B+1} D_{B+1}] \tau + \varepsilon_\tau,$$

where $D_1 = 1$ for $\tau \geq 1$, $D_b = 1$ for $\tau \geq \tau_{b-1}$, $b = 2, \dots, B+1$, and ε_τ is an AR(1) process. Then, for $\tau_{b-1} < \tau \leq \tau_b$, $\gamma_\tau^t = \sum_{i=1}^b \Gamma_i$ and $z_\tau = \varepsilon_\tau$. This construction imposes the orthogonality of γ^t and z and minimizes the sum of the squared transitory shocks.

8.4.2 Kim Filter

An alternative way to discipline the decomposition of productivity growth into trend and transitory components is to apply the Kim filter as described in Section 8.3.2. If the economic

agents in the model know the underlying processes for γ^t and z but only see the realization of productivity growth γ^a , the Kim filter could be used to solve the signal extraction problem.

Table 1: Moments of High-Frequency Fluctuations: U.S. 1950:1 - 2005:1

	Standard Deviation	SD relative to Y	Correlation with Y	Correlation with A	First-order Autocorrelation
Y	1.56	1	1	0.58	0.83
C	1.18	0.76	0.77	0.46	0.76
I	7.44	4.77	0.84	0.48	0.79
N	1.70	1.09	0.86	0.11	0.88
Y/N	0.87	0.56	0.12	0.83	0.70
r	0.33	0.21	0.66	0.664	0.74
A	0.92	0.59	0.58	1	0.74

The variables are GDP (Y), consumption (C), investment (I), hours worked (N), labor productivity (Y/N), the net realized return to capital (r), and TFP (A). All quantities are in real per capita terms, and all time series (except returns to capital) are in logs.

Table 2: Moments of Lower-Frequency Fluctuations: U.S. 1950:1 - 2005:1

	Standard Deviation	SD Relative to Y	Correlation with Y	Correlation with A	First-order Autocorrelation
Y	3.21	1	1	0.92	0.997
C	2.40	0.75	0.76	0.58	0.997
I	6.21	1.94	0.49	0.47	0.995
N	3.82	1.19	-0.31	-0.61	0.998
Y/N	5.71	1.78	0.77	0.93	0.999
r	0.61	0.19	0.38	0.19	0.997
A	4.67	1.45	0.92	1	0.999

All quantities are in real per capita terms, and all time series (except returns to capital) are in logs.

Table 3: Parameters for Textbook RBC Model

σ	β	η	ν	b	α	δ	μ_γ	ρ_z	σ_z
∞	0.987	1.0	1.5	30	0.333	0.015	1.0052	0.95	0.0105

Table 4: Avg. Moments of High-Freq. Fluctuations: Textbook RBC

	Standard Deviation	SD Relative to Y	Correlation with Y	Correlation with A	First-order Autocorrelation
Y	1.07	1	1	0.998	0.69
C	0.36	0.33	0.92	0.89	0.77
I	4.08	3.80	0.99	0.99	0.68
N	0.30	0.28	0.98	0.99	0.68
Y/N	0.78	0.72	0.997	0.99	0.70
r	0.04	0.03	0.97	0.98	0.68
A	0.87	0.81	0.998	1	0.68

Table 5: Avg. Moments of Lower-Freq. Fluctuations: Textbook RBC

	Standard Deviation	SD Relative to Y	Correlation with Y	Correlation with A	First-order Autocorrelation
Y	2.08	1	1	0.98	0.997
C	1.51	0.73	0.88	0.79	0.998
I	5.61	2.70	0.88	0.95	0.996
N	0.40	0.19	0.73	0.84	0.995
Y/N	1.81	0.87	0.98	0.94	0.997
r	0.05	0.02	0.43	0.58	0.996
A	1.42	0.69	0.98	1	0.996

Table 6: Parameters for Baseline “Living Standard” Model

σ	β	η	ν	b	ϕ_1	α	δ
1.0	0.987	0.33	1.5	20	0	0.333	0.015
	μ_γ	σ_γ	P	ρ_z	σ_z		
	1.0047	0.0022	0.0144	0.88	0.0099		

Table 7: Avg. Moments of High-Freq. Fluctuations: Living Standard

	Standard Deviation	SD Relative to Y	Correlation with Y	Correlation with A	First-order Autocorrelation
Y	1.06	1	1	0.99	0.66
C	0.46	0.43	0.86	0.85	0.70
I	3.86	3.64	0.97	0.96	0.65
N	0.37	0.35	0.98	0.97	0.66
Y/N	0.70	0.66	0.99	0.99	0.67
r	0.04	0.03	0.97	0.99	0.66
A	0.82	0.77	0.99	1	0.66

Table 8: Avg. Moments of Lower-Freq. Fluctuations: Living Standard

	Standard Deviation	SD Relative to Y	Correlation with Y	Correlation with A	First-order Autocorrelation
Y	3.28	1	1	0.94	0.998
C	2.79	0.85	0.95	0.85	0.999
I	6.06	1.85	0.90	0.91	0.997
N	0.51	0.16	0.34	0.17	0.997
Y/N	3.15	0.96	0.98	0.96	0.998
r	0.07	0.02	0.43	0.65	0.997
A	2.50	0.76	0.94	1	0.998

Table 9: High-Frequency minus Lower-Frequency Labor Moments

	ϕ_1	λ	Correlation with Y	Correlation with A
Data			1.19	0.75
Baseline: Stochastic Trend	0	1	0.64	0.80
Consumption and Trend	0.5	1	0.41	0.45
“Catching up with Joneses”	1	1	0.30	0.22
Constant Trend	0	0	0.02	0.01
Accelerated Stochastic Trend	0	1.05	0.70	0.87
